## Abstract

In spite of the resurgence in ice nucleation research a comparatively small number of studies deal with the phenomenon of pre-activation in heterogeneous ice nucleation. Already fifty years ago, it was shown that various mineral dust and volcanic ash particles can be pre-activated to become nuclei for ice crystal formation even at temperatures as high as 270–271 K. Pre-activation was achieved under ice subsaturated conditions without any preceding macroscopic ice growth by just temporarily cooling the particles to temperatures below 228 K. A two-step mechanism involving capillary condensation of supercooled water and subsequent homogeneous freezing was proposed to account for the particles' enhanced ice nucleation ability at high temperatures. This work reinvestigates the efficiency of the proposed pre-activation mechanism in temperature-cycling experiments performed in a large cloud chamber with suspended particles. We find the efficiency to be highest for the clay mineral illite as well as for highly porous materials like zeolite and diatomaceous earth, whereas most aerosols generated from desert dust surface samples did not reveal a measurable pre-activation ability. The pre-activation efficiency is linked to particle pores in a certain size range. As estimated by model calculations, only pores with diameters between about 5 and 8 nm contribute to pre-activation under ice subsaturated conditions. In contrast to the early study, pre-activation is only observed for temperatures below 260 K. Above that threshold, the particles' improved ice nucleation ability disappears due to the melting of ice in the pores.

## 1 Introduction

The microphysical processes leading to the formation of ice particles in the Earth's atmosphere are still poorly understood. As emphasised by the most recent report of the Intergovernmental Panel on Climate Change (Boucher et al., 2013), the accurate parameterisation of such microphysical processes is essential for the reliable simulation of

clouds in modern climate models. Only a minor subset of the atmospheric aerosol particles is able to act as ice nucleating particles (INPs), thereby promoting ice formation at lesser supersaturation or supercooling compared to homogeneous ice nucleation (Hoose and Möhler, 2012; Murray et al., 2012). Amongst this subset, an even smaller fraction of aerosol particles can trigger the glaciation of supercooled cloud droplets at temperatures higher than 258 K, most of them supposed to be composed of biological material (Murray et al., 2012; Prenni et al., 2009).

A potential mechanism that can increase the number concentration of INPs at warm temperatures is pre-activation, denoting the enhanced ice nucleation ability of an INP after its exposure to low temperature and/or its prior involvement in an ice nucleation event (Knopf and Koop, 2006; Pruppacher and Klett, 1997; Vali, 2008). In the latter case, it is argued that small pockets of ice can survive in pores or cracks at the particle surface even in an ice-subsaturated environment after the sublimation of the ice cloud from the preceding nucleation event (Mossop, 1956). These ice pockets represent sites where macroscopic ice crystals can easily grow again when the INP is again exposed to ice-supersaturated conditions in a succeeding nucleation event. Almost 50 years ago, it was shown that by a two-step mechanism of pore condensation of supercooled water and subsequent homogeneous freezing, pre-activated INPs with such ice pockets can also be formed in cold and dry air without the prior nucleation of macroscopic ice crystals at high humidity (Higuchi and Fukuta, 1966). These experiments were conducted with the INPs deposited onto a metal foil. As an example, 10 % of kaolin and even close to 100 % of montmorillonite particles were pre-activated to become INPs at 258 K by temporarily cooling them below 228 K in an environment that was subsaturated with respect to ice. After further warming above 258 K, the fraction of particles that retained their pre-activation decreased due to the melting of ice in the pores (Fukuta, 1966; Higuchi and Fukuta, 1966), but a 0.1 % fraction of pre-activated INPs was still present at temperatures as high as 270–271 K.

For decades, no follow-up studies on the suggested two-step pore condensation and freezing (PCF) mechanism were undertaken. Only three years ago, new experiments

Interactive Discussion

revealed that crystals of three organic model substances nucleated and grew in a surface cavity via the PCF mechanism from saturated vapour, i.e., without the need for supersaturation in the gas phase (Kovács et al., 2012). Shortly later, it was proposed that many observed ice nucleation events previously ascribed to the deposition ice nucleation mode, which by definition proceeds without prior formation of a liquid (Vali et al., 2015), could also be due to the PCF mechanism (Marcolli, 2014). This suggestion was based on the observation that many INPs reveal a strong increase in their ice nucleation ability just below the homogenous freezing temperature of supercooled water at 237 K. In cloud chamber experiments at our own laboratory, we have recently unravelled a pre-activation pathway which involves temperature cycling of INPs that have crystallised from aqueous solution droplets (Wagner et al., 2014). Here, residuals of the aqueous solution are trapped within the crystals and can freeze when cooled below their respective homogeneous or heterogeneous freezing temperature. This leads to the formation of ice pockets in the crystalline INPs, which can act as efficient sites for ice growth even at warmer temperatures where the intrinsic heterogeneous ice nucleation ability of the unprocessed INPs is very low. In contrast to the PCF mechanism, however, the origin of the ice pockets in these experiments is residual water enclosed in the crystallised aqueous solution droplets and not the capillary condensation of water vapour on a dry particle surface at a relative humidity ( $RH_w$ ) below water saturation. In view of the resurged interest in the PCF mechanism, we considered it timely to perform a novel experimental study on its efficiency using the large aerosol and cloud chamber facility AIDA (Aerosol Interaction and Dynamics in the Atmosphere), which enables long-term processing of suspended INPs under well-defined temperature and  $RH_w$  conditions and where the modification of the ice nucleation ability of the INPs can be investigated by adiabatic expansion cooling experiments (Wagner et al., 2006).

In this contribution, we report on the results of the first systematic study on the pre-activation of INPs under ice subsaturated conditions since the original work in 1966. As a benchmark, we first tested aerosol particles with a highly porous structure, like zeolite (Janssen et al., 2002) and diatomaceous earth particles (Korunic, 1998), where

we expected the efficiency of the PCF mechanism to be highest. We then compared these results to those obtained for atmospherically abundant INPs like mineral dust, volcanic ash, and soot particles. Our article is organised as follows: Sect. 2 describes the instrumentation of the AIDA aerosol and cloud chamber and presents the investigated materials. In Sect. 3.1, we introduce the applied experimental procedure and the observed pre-activation phenomenon based on the measurement data for zeolite particles. Thereafter, we summarise the pre-activation efficiency measured for all substances in Sect. 3.2. Detailed measurement data for those substances are given in Appendices A–E. In Sect. 4, we analyse the pre-activation data based on model calculations of the water condensation, freezing, and melting of ice in pores. Section 5 explores the atmospheric implications of our findings and Sect. 6 concludes our article with a summary.

## 2 Methods

### 2.1 Instrumentation

The AIDA facility consists of a 84.3 m<sup>3</sup> sized aluminium chamber that is housed in an isolating containment whose temperature can be controlled between 333 and 183 K (Möhler et al., 2003; Wagner et al., 2006). A powerful mixing fan placed at the bottom of the chamber was continuously in operation, providing homogeneous conditions in terms of temperature, relative humidity, as well as aerosol and cloud particle number concentrations throughout the chamber volume. The mean AIDA gas temperature was computed from the average of 11 thermocouple sensors arranged vertically at different height levels of the chamber. Water vapour concentrations, transformed into RH<sub>w</sub> and RH<sub>ice</sub> data based on the formulations by Murphy and Koop (2005), were measured in situ by a tunable diode laser spectrometer (Fahey et al., 2014). The number concentrations of the aerosol particles were measured with a condensation particle counter (CPC3010, TSI), and their size distributions recorded by a scanning mobility parti-

Interactive Discussion

for particles with a high degree of porosity. Exemplary ESEM images of filter-collected CBV400, CBV100, and diatomaceous earth particles are shown in Figs. 1 and 2. The ensemble image b (Fig. 1) reveals that the overall shape of the CBV400 particles is rather compact. A common feature is the occurrence of agglomerated crystals as exemplified in image c. An indication for the substantial porosity of the particles is their high transparency to the electron beam. In image c, e.g., one can clearly discern one of the holes of the Nuclepore filter behind the deposited CBV400 crystal. The enlarged image a gives an idea of the mesopore system of CBV400, showing numerous open pores at the surface of the particle.

The general habit of the CBV100 particles was observed to be very similar to that of the CBV400 particles. Albeit lacking the larger internal mesoporous network, the CBV100 particles' surface is not completely smooth but reveals a certain degree of roughness due to small cracks and steps. In addition to the microporous network of CBV100, these surface sites as well as void spaces between crystal agglomerates (image d in Fig. 2) may also allow for the condensation of supercooled water at  $RH_w < 100\%$  and explain a potential pre-activation ability. The two selected ESEM images e and f of diatomaceous earth (Fig. 2) underline the extremely complex structure of these particles. Apart from large-scale hole patterns, the recordings show clear evidence for small-scale surface roughness and porosity. Our material is similar to another commercial diatomaceous earth sample that was recently probed for its light scattering properties (Alexander et al., 2013).

### 2.2.2 Mineral dust, volcanic ash, and soot particles

In addition to the zeolite and diatomaceous earth particles, we chose six further types of INPs for the pre-activation experiments. The intrinsic heterogeneous ice nucleation abilities of these substances have been characterised in previous AIDA measurement campaigns. The materials include: (i) an Illite NX sample (Arginotec, NX Nanopowder) that was recently distributed as a surrogate for natural desert dusts in a comprehensive laboratory study of ice nucleation measurement techniques (Hiranuma et al., 2015), (ii)

and EY01, the particle density,  $\rho_p$ , was set to  $2.6 \text{ g cm}^{-3}$  and the dynamic shape factor,  $\chi$ , was set to 1.2. Reduced  $\rho_p$  values of 1.9 and  $2.3 \text{ g cm}^{-3}$  were required to combine the size spectra of the porous zeolite materials CBV400 and CBV100, respectively. The combined size spectrum of the diatomaceous earth particles was obtained with  $\rho_p = 2.3 \text{ g cm}^{-3}$  and  $\chi = 1.5$ .

### 2.3 Operation of the AIDA chamber

Before the start of aerosol injection, the inner walls of the AIDA chamber were partially coated with an ice layer and the vessel was filled with particle-free synthetic air to ambient pressure. The ice-coated walls controlled the prevailing  $\text{RH}_{\text{ice}}$  value in the chamber interior to typically 95%. The slightly ice-subsaturated conditions are the result of some internal heat sources, causing that the average gas temperature of the chamber is a few tenths of a Kelvin higher than the wall temperature.

After aerosol injection as described in Sect. 2.2.3, the aerosol particles were either immediately probed on their intrinsic heterogeneous ice nucleation ability at a given temperature, or they were probed after overnight temperature cycling to investigate the efficiency of the PCF pre-activation mechanism under ice-subsaturated conditions, as detailed in Sect. 3.1. Temperature adjustments of the AIDA chamber during temperature cycling were usually accomplished at a rate of  $5 \text{ K h}^{-1}$  during cooling and  $2.5 \text{ K h}^{-1}$  during warming. To achieve ice formation, supersaturations with respect to ice were induced by expansion cooling, i.e., a controlled reduction of the chamber pressure with a mechanical pump operated at a volume flow rate of typically  $2.5 \text{ m}^3 \text{ min}^{-1}$ . This established initial cooling rates for the chamber atmosphere of about  $3 \text{ K min}^{-1}$ . The cooling rates were then steadily decreasing during continued pumping due to the increasing heat flux from the chamber walls, whose temperature remained almost unchanged. For a particular experiment (Sect. 5.3), we used an evacuated,  $4 \text{ m}^3$  sized aerosol preparation chamber as an additional expansion volume, inducing an almost instantaneous drop of the gas temperature by another 2 K in the later course of expansion cooling.

### 3 Results

#### 3.1 The pre-activation phenomenon: detailed measurement data for the CBV400 particles

Figure 3a and b shows the intrinsic heterogeneous ice nucleation ability of unprocessed CBV400 crystals that have been dry-dispersed into the AIDA chamber at 251 and 228 K, respectively. After injection, the aerosol particles were subjected to an adiabatic expansion, as performed by a controlled reduction of the chamber pressure (Sect. 2.3). This leads to a decrease in the gas temperature (red lines) and an increase in the relative humidity with respect to ice,  $RH_{ice}$  (black lines). The expansion run started at 251 K (Fig. 3a) proved the CBV400 particles to be very inefficient INPs. There was no formation of ice particles via deposition nucleation before water saturation has been exceeded during the expansion, upon which the aerosol particles acted as cloud condensation nuclei and a dense cloud of supercooled water droplets was formed (vertical dashed line). The cloud droplets grew to diameters of about 10  $\mu\text{m}$ , as inferred from the scattering signals of the optical particle counters (OPCs, dark-yellow dots). Nucleated ice crystals grew to larger diameters than the cloud droplets and can therefore separately be identified in the OPC data sets, enabling the calculation of the ice-active fraction of the aerosol population,  $f_{ice}$  (blue lines). As evident from the OPC data in Fig. 3a, only a tiny fraction of less than 0.1 % of the immersed CBV400 particles is ice-active in the immersion freezing mode in the temperature range from 246 to 243 K. The heterogeneous ice nucleation ability changed profoundly when the CBV400 particles were probed in an expansion run that was started at a temperature below 237 K (Fig. 3b). Here, almost immediately after the start of expansion cooling at time zero, a dense ice cloud was formed at a  $RH_{ice}$  threshold of only 102 %. More than 40 % of the CBV400 particles acted as INPs even though the peak  $RH_{ice}$  value during the expansion run never exceeded a value of 105 %. It is the sudden appearance of this extraordinarily high ice nucleation ability just below 237 K which puts in doubt the assignment of this nucleation mode to a deposition nucleation mechanism, given that there is no a priori

reason why this pathway should abruptly be inefficient for temperatures above 237 K (Marcolli, 2014; Pruppacher and Klett, 1997). More likely, the ice nucleation mode evident in Fig. 3b is due to the depositional growth of ice pockets which have already been formed before by the PCF mechanism.

As an indirect proof for the PCF mechanism, we have performed the following pre-activation experiment. The CBV400 particles were dry-dispersed into the AIDA vessel at 253 K, upon which the chamber was cooled to 228 K and warmed to 250 K. During temperature cycling, the chamber air remained slightly subsaturated with respect to ice with a typical  $RH_{ice}$  of 95 % (see Sect. 2.3). No intermediate expansion cooling runs were conducted, meaning that the aerosol particles were not subjected to ice-supersaturated conditions where macroscopic ice crystals could have grown. Only after warming to 250 K, the zeolite particles were probed for their ice nucleation ability in an expansion cooling run whose data are shown in Fig. 3c. In contrast to the unprocessed CBV400 particles that were almost ice-inactive when probed at the same temperature (Fig. 3a), the pre-activated particles gave rise to a pronounced nucleation mode that formed at a  $RH_{ice}$  threshold of about 102 %. We assign this mode to depositional growth of ice held in the pores of the zeolite particles, which has been formed by the PCF mechanism during temperature cycling. To our knowledge, this is the first demonstration of pre-activation under ice-subsaturated conditions in an experiment with suspended particles. The fraction of ice-active CBV400 particles is about 4 %. The macroscopic ice crystals that had formed in the expansion run were then rapidly sublimed by the addition of dry synthetic air, which led to a temporary decrease in  $RH_{ice}$  to a minimum value of about 90 %. As pore ice was shown to be stable even down to much lower  $RH_{ice}$  values of 40 to 5 % (Knopf and Koop, 2006), the experiment was continued with the same aerosol load to investigate up to which temperature the pre-activation behaviour can still be observed, i.e., to determine when the pore ice starts to melt and the improved ice nucleation ability disappears.

For that purpose, the AIDA temperature was stepwise increased by about 3 K and expansion cooling runs were conducted at the higher temperatures as well. When probed

at 253 and 256 K, the CBV400 particles were still ice-active in the depositional growth mode, however with reduced number fractions of only 1.7 and 0.2% of the particles, respectively. After further warming to 259 K (Fig. 3d), the depositional growth mode has disappeared, and only a small number of ice crystals was formed after the droplet activation of the zeolite particles. Albeit small, the ice-active fraction is still higher compared to the intrinsic ice nucleation ability when the unprocessed CBV400 particles are directly probed at that temperature without temporary cooling. We observed similar behaviour for a variety of compounds (additional examples are discussed in Appendices A–E), which leads us to conclude that the small ice nucleation mode shown in Fig. 3d is due to pre-activation as well. We tentatively assign it to the condensational growth of residual ice that is deeply captured in pores and cannot grow by water vapour deposition on the time scale of our experiments but only when getting in contact with liquid supercooled water after the droplet activation.

We performed a further pre-activation experiment where the CBV400 particles were again injected at 253 K, cooled to 228 K, but then directly warmed to 259 K to perform an expansion cooling run at that temperature. We observed a similar nucleation mode due to condensational ice growth after droplet activation as shown in Fig. 3d, underlining that the intermediate expansion runs conducted at 250, 253, and 256 K in the previous experiment did not lead to a loss of pre-activated particles, but that the pre-activation efficiency is actually significantly reduced at 259 K.

### 3.2 Summary of the pre-activation behaviour for all substances

Figure 4 summarises the pre-activation behaviour for the other compounds investigated. For each aerosol type, we applied the same temperature cycling, i.e., injection at 253 K and temporary cooling to 228 K. The filled bars denote the ice-active fractions of the pre-activated particles in the depositional growth mode at  $RH_w$  below 100% at various temperatures after warming, and those without colour filling represent the condensational ice growth mode after droplet activation. Partly, both modes were observed successively in a single expansion cooling experiment. This happened when the num-

ber concentration of ice crystals formed by depositional growth was so small that the water vapour supersaturation was not efficiently depleted, so that water saturation was exceeded upon continued pumping and the condensational ice growth mode could become active. Additional data from the AIDA experiments are provided in Appendices A–E to support that the ice-active fractions depicted in Fig. 4 are due to pre-activation and not related to the intrinsic heterogeneous ice nucleation ability of the aerosol particles.

Let us first compare the pre-activation behaviour of the mesoporous CBV400 particles with that of the second zeolite sample, namely the microporous CBV100 particles. As the melting temperature of ice is expected to decrease with the pore diameter (Marcolli, 2014), we have performed the initial pre-activation run with the microporous CBV100 particles already at a lower temperature of 246 K after temperature cycling. Here, 1 % of the pre-activated particles were ice-active in the depositional growth mode (Fig. 4). At 250 K where the first pre-activation run with the CBV400 particles was conducted, only 0.08 % of the CBV100 particles still showed the depositional ice growth mode, followed by a somewhat larger condensational ice growth mode after droplet activation ( $f_{\text{ice}} = 0.6\%$ ). After further warming to 253 K, the pre-activation mode has all but disappeared, showing that the pre-activation efficiency of the microporous CBV100 particles is much smaller compared to the mesoporous CBV400 sample.

Two samples that show a similar pre-activation efficiency as CBV400 are diatomaceous earth and illite NX. Amongst the CBV400, illite NX, and diatomaceous earth samples, the illite NX particles show the highest ice-active fraction of almost 6 % for pre-activation at a temperature of 250 K (Fig. 4). The diatomaceous earth particles feature the most dominant retention of the pre-activation behaviour at warmer temperatures, being the only sample where even after warming to 259 K a small depositional ice growth mode could still be observed. Amongst the four natural dust and volcanic ash samples, only the CID particles showed a small pre-activation mode at 250 K with  $f_{\text{ice}} = 0.5\%$  in the depositional growth mode (Fig. 4). For SD2, ID, and EY01, the heterogeneous ice nucleation ability was not enhanced after temperature cycling. A small pre-

activation ability was measured for the GSG soot particles at temperatures up to 250 K. This pre-activation behaviour was only observed when the freshly emitted, fractal-like soot agglomerates were immediately subjected to the temperature cycling program. In a second type of experiment, the soot particles were first processed by a droplet activation run at 253 K before cooling them to 228 K. Water condensation and evaporation leads to restructuring and collapsing of the soot aggregates (Ma et al., 2013). For these water-processed GSG soot particles, the pre-activation ability disappeared.

## 4 Discussion

### 4.1 Theoretical considerations on the water condensation, freezing, and melting of ice in pores

Figure 5a shows the time series of the AIDA temperature during a typical pre-activation experiment. Three different processes have to be considered for the interpretation of the observed pre-activation behaviour, namely the capillary condensation of supercooled water, the freezing of capillary-held water, and the melting of ice in the capillaries when increasing the temperature. The humidity and temperature conditions for the occurrence of these processes depend on the pore diameter, as outlined in the following three sections.

#### 4.1.1 Capillary condensation of supercooled water

As shown by Marcolli (2014), the measured onset relative humidities for the capillary condensation of water in pores of different mesoporous materials can adequately be described by the inverse Kelvin equation (Eq. 1).

$$\ln \frac{e_w}{e_{\text{sat}, w}} = - \frac{4M_w \sigma_w / a}{RT \rho_w D} \quad (1)$$

Interactive Discussion

Equation (1) describes the reduction of the saturation water vapour pressure over a concave water meniscus,  $e_w$ , in relation to that over a flat water surface,  $e_{\text{sat}, w}$  (Pruppacher and Klett, 1997).  $M_w$  is the molecular weight of water,  $\sigma_{w/a}$  the surface tension for a water-humid air interface,  $R$  the universal gas constant,  $\rho_w$  the density of water,  $T$  the absolute temperature, and  $D$  the diameter of curvature of the water surface in a capillary. The quotient  $e_w/e_{\text{sat}, w}$  equals the saturation ratio of moist air with respect to a plane water surface. Using Eq. (1), the  $\text{RH}_w$  values for the onset of capillary condensation of supercooled water were calculated for four different temperatures to predict the upper size limit of pores that can fill with water at the  $\text{RH}_w$  conditions prevalent in the AIDA chamber (Fig. 5b). We took into account temperature-dependent parameterisations for  $\sigma_{w/a}$  and  $\rho_w$  given by Pruppacher and Klett (1997), but ignored the Tolman correction for the size dependence of surface tension (Rao and McMurry, 1990).

Point A in Fig. 5b represents the starting point of the experimental trajectory, denoting the prevalent value of  $\text{RH}_w$  when the aerosol particles were injected into the chamber at a temperature of 253 K (corresponding to  $\text{RH}_{\text{ice}} = 95\%$  at the same temperature). Similarly, point B denotes the somewhat lower value for  $\text{RH}_w$  when the chamber was cooled at constant  $\text{RH}_{\text{ice}}$  of 95% to the homogeneous freezing temperature of supercooled water at 237 K. According to the inverse Kelvin equation, the maximum diameter of pores that can fill with water is about 11 nm after injection at 253 K, and decreases to about 8 nm when the chamber is cooled to 237 K where homogeneous freezing of capillary-held supercooled water could lead to the formation of ice in the pores. Ice formation could also involve slightly larger pores, but this would require that the capillary-held water already freezes heterogeneously at a temperature higher than 237 K (point B\*).

#### 4.1.2 Freezing of capillary-held water

In the next step, we have to analyse whether the homogeneous (or heterogeneous) freezing of supercooled water is not impeded for narrow pore diameters. Marcolli (2014)

has adopted a quantity from Classical Nucleation Theory to describe the freezing and melting of ice in pores, namely the critical embryo size for homogeneous ice nucleation in the pores. Only if the pore dimension exceeds the critical embryo size, the ice embryo has a higher tendency to grow, which reduces the free energy of the system, than to shrink, which increases the free energy (Pruppacher and Klett, 1997). Ice formation should therefore be inhibited in pores where an ice embryo cannot grow beyond the critical embryo size, even if the temperature is below 237 K.

The critical radius of a spherical ice embryo for homogeneous ice nucleation,  $r_c$ , for which the Gibbs free energy of embryo formation within the liquid phase has its maximum, is given by (Murray et al., 2012):

$$r_c = \frac{2M_w \sigma_{i/w}}{RT \rho_i \ln \frac{e_{\text{sat}, w}}{e_{\text{sat}, i}}} \quad (2)$$

In Eq. (2),  $\sigma_{i/w}$  is the interfacial tension between water and the ice embryo,  $\rho_i$  the density of ice, and  $e_{\text{sat}, i}$  the saturation water vapour pressure over a flat ice surface. Using Eq. (2), we have calculated the temperature-dependent pore diameters needed to incorporate a critical ice embryo as  $2r_c + 2t$ , where  $t$  accounts for a non-freezing quasi-liquid layer between pore wall and ice embryo (Marcolli, 2014). In this computation,  $t$  was set to 0.6 nm (Marcolli, 2014), temperature-dependent  $\rho_i$  values were obtained from the parameterisation given by Pruppacher and Klett (1997),  $e_{\text{sat}, w}$  and  $e_{\text{sat}, i}$  were calculated according to the formulations by Murphy and Koop (2005), and  $\sigma_{i/w}$  was taken from the fit of measured homogeneous ice nucleation rate coefficients presented by Zobrist et al. (2007).

The result of the computation is shown in Fig. 5c. Regarding our pre-activation experiments, this curve defines the lower threshold size of pores where ice formation due to freezing of capillary-held water can occur at a given temperature. At 237 K (point B), this size threshold is about 4 nm, and it further decreases to about 3 nm at 228 K, the minimum temperature during the experiment (point C). Here, all aerosol particles with pores in the diameter range from 3 to 8 nm therefore have the chance to incorporate

ice due to the PCF mechanism even in an ice-subsaturated environment (red hatched area in Fig. 5c). These ice pockets can trigger the depositional ice growth mode when the aerosol particles are directly probed in an expansion cooling experiment started at 228 K. In our pre-activation experiments, however, we want to investigate the survival of such ice pockets and their contribution to depositional ice growth at warmer temperatures. Therefore, we have to consider as the third important process the melting of ice when increasing the temperature in the pre-activation experiments.

### 4.1.3 Melting of ice in pores

For describing the temperature dependence of the melting of ice in pores, the same curve as for the freezing of ice applies (Marcolli, 2014). Once the diameter of a certain pore gets smaller than the critical embryo size during warming, the ice in the pore should melt because shrinkage of the ice phase would lead to a decrease in the free energy of the system. Point D at 257 K (Fig. 5c) therefore denotes the melting temperature of ice in the largest pores in which ice pockets could have been formed via the PCF mechanism in the case of homogeneous freezing at point B. Above that temperature, the pre-activation behaviour should disappear. In the case of heterogeneous freezing at point B\*, the temperature threshold for the disappearance of the pre-activation ability could be a few degrees higher (point D\*), because ice in larger pores with a higher melting temperature were present.

## 4.2 Application of the model calculations to the observed pre-activation behaviour

How do the theoretical considerations from Sect. 4.1 apply to our experimental findings from Fig. 4? In good agreement with theory, pre-activation, if observed, is only retained for temperatures below 260 K. Let us consider e.g. the mesoporous zeolite CBV400 particles that have a broad range of pore diameters up to 20 nm. For a pore size of 20 nm, the predicted pore ice melting temperature is about 267 K (Fig. 5c). In previous

Interactive Discussion

experiments where the CBV400 particles were probed in a suspension and water could penetrate in all pores regardless of their size, the maximum of the endothermic peak in the DSC heating scan corresponding to the melting of ice in the mesopores was indeed observed above 260 K (Janssen et al., 2004). In an ice-subsaturated environment, however, water condensation and subsequent homogeneous freezing is limited to pores with diameters smaller than 8 nm (point B in Fig. 5b). In good accordance with the expected upper ice melting temperature indicated by point D in Fig. 5c, the improved ice nucleation ability for the CBV400 particles in the pre-activation experiment is therefore already significantly reduced after raising the temperature from 253 to 256 K, and the last small pre-activation mode is observed at 259 K. The compound that shows the highest pre-activation efficiency after warming to 259 K is diatomaceous earth. In contrast to the CBV400 particles which do not possess any pronounced intrinsic heterogeneous ice nucleation ability above 237 K, the unprocessed diatomaceous earth particles showed a very strong immersion freezing mode at about 240 K (see Fig. C1). This heterogeneous ice nucleation mode could increase the freezing temperature of the capillary-held water during pre-activation (freezing at point B\* instead of B), and thereby increase the upper melting temperature of ice in the pores (melting at point D\* instead of D).

Regarding the microporous CBV100 material, the previous experiments where the CBV100 particles were probed in a suspension did not reveal any freezing peaks of pore water down to a temperature of 213 K (Janssen et al., 2004). Due to the smaller pore sizes of at most 1.2 nm compared to the mesoporous CBV400 particles, freezing of capillary-held water in CBV100 is inhibited for temperatures above 213 K (Fig. 5c). How can we then explain the small pre-activation ability observed for CBV100 (Fig. 4) although the minimum temperature during our experiment was only 228 K? As pre-activation cannot be ascribed to ice formation in the internal microporous network of CBV100, it must be related to other, larger scaled surface characteristics like cracks, steps, or empty spaces between aggregate particles which could also enable the PCF mechanism (see Sect. 2.1.1). Also in the case of clay minerals like illite, the respective

sites for pore condensation and freezing are void spaces arising from the interleaving of plates in the aggregate particle (Aylmore and Quirk, 1967). For soot particles, capillary condensation most likely occurs in the empty spaces between aggregate primary particles (Marcolli, 2014). The compaction of soot aggregates during droplet activation therefore destroys their pre-activation ability.

Electron micrographs of the employed natural dust and volcanic ash samples showed particles with irregularities in the surface and partly aggregate-like structure (Linke et al., 2006; Steinke et al., 2011), i.e., prerequisites for making these materials prone to the PCF pre-activation mechanism as well. However, pre-activation by the depositional ice growth mode at temperatures between 245 and 260 K requires the availability of pores with diameters between about 5 and 8 nm (Fig. 5c). Apparently, most of the investigated natural dust and volcanic ash particles do not contain pores in this particular size regime due to the absence of pre-activation. The intrinsic heterogeneous ice nucleation ability of a certain compound at 228 K is a useful indicator to assess its potential pre-activation ability after temperature cycling. Amongst the SD2, ID, CID, and EY01 samples, all particles revealed a heterogeneous ice freezing mode below water saturation when injected and probed in an expansion run started around 228 K (Fig. E1). Only for the CID particles, however, the onset of ice formation was close to ice saturation as observed for the CBV400 particles (Fig. 3b). This indicates that ice-filled pores were already formed by the PCF mechanism at  $RH_{ice} < 100\%$  before the start of the expansion run, which is the prerequisite for observing pre-activation under ice subsaturated conditions. For the other compounds, a distinct supersaturation threshold was needed to induce ice formation, indicating that there were initially no ice-filled pores available where ice crystals could immediately grow after exceeding  $100\%$   $RH_{ice}$  upon expansion cooling. Consequently, these compounds did not reveal any pre-activation behaviour after temperature cycling under ice subsaturated conditions.

Even for the compounds where pre-activation was detected, only a small percentage of the overall aerosol population acted as pre-activated INPs between 245 and 260 K, showing that only a subset of the particles contained pores in the narrow range of

appropriate diameters. The maximum of the differential pore-size distribution for an illite sample, e.g., was located at plate separations between 2 and 4 nm whereas pores larger than 5 nm were much less frequent (Aylmore and Quirk, 1967). Smaller ice-filled pores can contribute to the dominant depositional ice growth mode observed for illite NX particles at  $T < 237$  K (Fig. B1,  $f_{\text{ice}} = 58\%$ ), but only those larger than 5 nm are responsible for pre-activation at 250 K ( $f_{\text{ice}} = 6\%$ ). In the former study by Higuchi and Fukuta (1966), much higher number fractions of the investigated particles were found to retain their pre-activation ability upon warming, even at temperatures above 260 K where in the present study the improved ice nucleation ability had completely disappeared. We currently cannot give an explanation for this difference.

## 5 Atmospheric implications

### 5.1 Mechanism of heterogeneous ice nucleation at $T < 237$ K

Apart from the impact on heterogeneous ice formation above 237 K, our results provide new insights into the microphysics of the ice nucleation mechanism at lower temperatures. The temperature cycling experiments prove that the pores of certain compounds like illite NX, CBV400, and diatomaceous earth can fill with ice at  $\text{RH}_{\text{ice}} < 100\%$  and  $T < 237$  K. Cloud ice crystals can then easily form on the pre-activated particles by depositional ice growth at  $\text{RH}_{\text{ice}} > 100\%$  without any activation threshold or specific nucleation site as needed for the actual deposition nucleation process. For compounds that do not have ice-filled pores at ice-subsaturated conditions like SD2 and ID, it remains unclear whether ice formation at higher supersaturation thresholds is due to the PCF mechanism or “true” deposition nucleation without the participation of a liquid phase. An important factor may be the time scale of pore condensation in an uplifting air parcel, i.e., whether this process occurs instantaneously once the threshold relative humidity for a given pore size is surpassed or whether it proceeds more slowly and makes the contribution of the PCF mechanism to ice nucleation less probable. In

5 this regard, it would be important to investigate whether other extensively used INP counters like continuous flow diffusion chambers (CFDCs), which only have particle residence times on the order of a few seconds, would detect the same high ice nucleation efficiency for e.g. unprocessed CBV400 particles at  $T < 237$  K as inferred from the AIDA, where the aerosol particles reside at least for several minutes before the expansion run is started. In any case, the kinetics of the PCF mechanism needs to be studied in greater detail.

## 5.2 Heterogeneous ice nucleation at $T > 237$ K

10 Based on the pre-activation efficiencies shown in Fig. 4, it seems unlikely that the PCF mechanism under ice subsaturated conditions provides a substantial number of additional INPs at very high temperatures above 258 K. In agreement with theoretical considerations on the pore-size dependent thresholds for water condensation and ice melting, only narrow pores with ice melting temperatures below 260 K can contribute to pre-activation after temperature cycling at  $RH_{ice} < 100$  %. This is different from the previously detected pre-activation mechanism for crystallised aqueous solution droplets (Wagner et al., 2014). In that case, larger sized frozen solution pockets can remain encapsulated in the effloresced particles and survive up to the eutectic melting temperature, which for low soluble compounds like dicarboxylic acids is close to 273 K (Wagner et al., 2014).

15 20 The PCF pre-activation mechanism, however, can increase the efficiency of INPs at moderately high temperatures between 245 and 258 K where most unprocessed INPs only promote ice formation via immersion freezing above water saturation (DeMott et al., 2011). In contrast, pre-activation allows for depositional ice growth at a much lower ice supersaturation threshold. We identify three key issues for future experimental studies to elaborate the atmospheric importance of this process:

- 25 i. Focus on natural dust samples from the Bodélé Depression, consisting of fragments of diatomite sediments. Based on the outcome of our temperature cycling

**Pre-activation of ice nucleating particles**

R. Wagner et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

experiments with diatomaceous earth, we expect that such dust samples show a much higher pre-activation efficiency than those probed in the present study (ID1, SD2, and CID).

- ii. Coating experiments with inorganic (sulphate, nitrate) and organic material. Will atmospherically relevant coating thicknesses reduce or even completely inhibit the pre-activation ability?
- iii. Variation of the relative humidity. Up to which lower  $RH_{ice}$  threshold pore ice will be stable (Knopf and Koop, 2006)?

In principle, the PCF pre-activation mechanism does not necessitate prior involvement in an ice nucleation event. Unlike in the laboratory where temperature cycling of aerosol particles without the formation of ice crystals can easily be performed, a preceding ice nucleation event might be necessary in the atmosphere to enable the transport of pre-activated aerosol particles to lower altitudes (Knopf and Koop, 2006; Roberts and Hallett, 1968). In other words, pre-activated particles with ice-filled pores may first contribute to high-altitude cirrus formation by the depositional ice growth mode. Larger ice crystals then fall out by sedimentation and release the pre-activated particles at lower altitudes after the evaporation of the ice crystals, but conserving the ice-filled pores.

Such cycling process was also proposed for the well-established pre-activation mechanism where INPs are involved in succeeding ice nucleation events (Roberts and Hallett, 1968), and it was suggested that pre-activation should be considered when modelling the long-range transport of INPs and their impact on cloud formation (Knopf and Koop, 2006). In a study on the atmospheric cycling of oxalic acid aerosol particles (Zobrist et al., 2006), it was stated that there was no suitable method to estimate which percentage of cirrus clouds in the atmosphere has previously undergone ice formation. To our knowledge, such modelling effort to estimate how often pre-activation occurs and affects the overall ice particle number concentrations has not yet been attempted. In lack of quantitative model simulations on the contribution of pre-activation

to ice cloud formation, we encourage studies to quantify the number concentration of pre-activated particles in atmospheric air masses by in situ measurements. In situ detection of pre-activated INPs by e.g. airborne CFDC instruments requires an inlet tube with the temperature kept at ambient conditions so that ice in the pores cannot melt prior to the actual measurement. At present, we are not aware of such studies in the literature.

### 5.3 Pre-activation in a deep convective cloud system

Another potential pathway for altitude and thereby temperature cycling of atmospheric aerosol particles which is of relevance for pre-activation includes deep convective clouds (Adler et al., 2013). In such a cloud system, the aerosol particles are first activated to cloud droplets at warm temperatures. The cloud droplets can freeze when the temperature drops below the homogeneous freezing temperature of supercooled water, and the cloud-processed aerosol particles are released in ice-subsaturated areas in the outflow of deep convection (Adler et al., 2013). In contrast to the PCF pre-activation mechanism at  $RH_{ice} < 100\%$ , droplet activation enables all pores of CCN active particles to be filled with water, regardless of their size. After homogeneous freezing and evaporation of the ice crystals, ice-filled pores with diameters larger than 8 nm and a concomitantly higher ice melting temperature should be conserved. We have simulated such cycling in deep convective clouds with zeolite CBV400 particles in the AIDA (Fig. 6a). For that purpose, an expansion cooling run with freshly injected CBV400 particles was started at 242 K. After about 4 K of cooling, the relative humidity has exceeded water saturation and the seed aerosol particles were activated to a cloud of supercooled water droplets (first vertical line). Only a small number fraction of the zeolite particles thereafter acted as immersion freezing ice nuclei. After further cooling by about 1 K, the gas temperature had approached the homogeneous freezing temperature of supercooled water (second vertical line). At that instance, a valve to an evacuated chamber of 4 m<sup>3</sup> volume was opened (see Sect. 2.3). The additional expansion led to a rapid decrease of the gas temperature by another 2 K, causing the entire

droplet cloud to glaciare. Afterwards, the ice crystals were sublimed by the addition of dry synthetic air and the AIDA chamber was warmed to 250 K and above to quantify the enhanced ice nucleation ability of the pre-activated, cloud-processed CBV400 particles.

In Fig. 6b, we compare the temperature-dependent ice-active fractions of CBV400 after PCF pre-activation by temperature cycling with those after cloud-processing, comprising droplet activation, freezing, and sublimation. The latter mechanism profoundly increases the pre-activation efficiency, suggesting that pores can more easily fill with water by droplet activation than by the condensation of water vapour in a subsaturated environment. As expected, the pre-activation ability after cloud-processing is conserved up to higher temperatures because larger pore diameters are involved, and thereby reaches the temperature regime where ice nucleation is usually ascribed to particles of biological origin only (Murray et al., 2012). Apart from deep convective clouds (Adler et al., 2013), recycling of ice nucleating particles was recently also taken into account to explain the maintenance of cloud ice production in Arctic mixed phase stratocumulus, however without considering pre-activation effects (Solomon et al., 2015). The potential importance of pre-activation by cloud-processing clearly stimulates further research of this mechanism with different aerosol types, with the AIDA chamber as an ideal platform to explore the processing of INPs in subsequent cloud formation cycles.

## 6 Summary

Understanding the microphysical processes that lead to the formation of ice particles in the Earth's atmosphere is of vital importance for the reliable simulation of clouds in modern weather and climate models. Much effort has recently been made to identify new aerosol types contributing to the atmospheric abundance of ice nucleating particles, e.g. biological materials like cellulose, bacteria, and marine diatoms. In this work, we have addressed a less investigated subject, namely the enhancement of the ice

nucleation ability of well-known and abundant ice nucleating particles like dust grains due to pre-activation. Temporary exposure to a low temperature (228 K) provokes that pores and surface cracks of the particles are filled with ice, which makes them better nuclei for the growth of macroscopic ice crystals at high temperatures (245–260 K).

This can in particular be important for the precipitation initiation in mixed-phase clouds because it potentially contributes to enhance the abundance of INPs at temperatures up to about 260 K. Above 260 K, the ice in the pores melts and the pre-activation of the aerosol particles is lost.

The pre-activation mechanism involves two steps: (i), the capillary condensation of supercooled water, and (ii), the subsequent homogeneous freezing of the capillary-held water. Pre-activation does not require that the aerosol particles are previously involved in an ice nucleation event. Once pre-activated, the ice kept in the pores can trigger ice formation just above ice saturation without requiring any distinct nucleation threshold or particular nucleation site. We showed that aerosol particles generated from powder samples of the clay mineral illite, diatomaceous earth, and zeolite could be pre-activated in this manner, whereas the majority of particles generated from natural dust and volcanic ash samples did not yield a measurable pre-activation. Model calculations suggest that the pre-activation ability is linked to pores of a certain dimension with diameters from about 5 to 8 nm. Our exploratory study stimulates further research to elaborate the quantitative impact of pre-activation on primary ice formation in tropospheric clouds, including further laboratory experiments, in situ observations, and cloud modelling.

**Appendix A: Ice nucleation experiments with CBV100**

Figure A1 compares the measurement data from the pre-activation experiments with CBV100 to those with CBV400, demonstrating the profoundly reduced pre-activation ability of the microporous zeolite material. Parts a and b show the expansion cooling runs started at 250 K after temporarily cooling the CBV400 and CBV100 particles to

Interactive Discussion

228 K. Whereas the pre-activated CBV400 particles give rise to a pronounced depositional ice growth mode (part a, same data as in Fig. 3c,  $f_{\text{ice}} = 3.7\%$ ), the CBV100 particles are barely ice-active ( $f_{\text{ice}} = 0.08$ ) in the regime between  $\text{RH}_{\text{ice}} = 100\%$  (first vertical line) and  $\text{RH}_{\text{w}} = 100\%$  (second vertical line). Only after the droplet activation of the CBV100 particles, significantly more ice crystals are observed with  $f_{\text{ice}} = 0.6\%$ . This is another example for what we called the condensational ice growth mode after pre-activation, because ice formation at this temperature was only observed after temperature cycling but not for the unprocessed zeolite particles. After further warming the AIDA chamber to 253 K, the CBV400 particles retain a high activity in the depositional ice growth mode with  $f_{\text{ice}} = 1.7\%$  (Fig. A1c), whereas the improved ice nucleation ability of the CBV100 particles almost disappeared (part d).

## Appendix B: Ice nucleation experiments with illite NX

In comparison with the zeolite particles, illite NX has a much higher intrinsic heterogeneous ice nucleation ability above 237 K (Hiranuma et al., 2015). It is therefore crucial to select an appropriate temperature where ice nucleation due to pre-activation can be clearly separated from the intrinsic ice nucleation behaviour. When probing the unprocessed illite NX particles in an expansion cooling experiment at 250 K (Fig. B1a), ice formation is solely due to immersion freezing after exceeding water saturation (vertical line). The ice-active fraction is below 1% for temperatures above 243 K, but then rapidly increases to 4% within a further Kelvin of cooling. Due to the absence of ice formation below water saturation, i.e., before water droplet formation, a temperature of 250 K is suitable to probe the pre-activation ability of the illite NX particles in the depositional ice growth mode after temperature cycling. Similar to CBV400 (Fig. 3b), the unprocessed illite NX particles show massive ice formation with  $f_{\text{ice}} = 58\%$  at very low ice supersaturation values when probed at  $T < 237$  K (Fig. B1b).

Two examples of the improved ice nucleation ability of the illite NX particles after temperature cycling are shown in parts c and d of Fig. B1. When probed at 250 K (part

c), the pre-activated illite NX particles provoke a strong depositional ice growth mode that forms at  $RH_{ice} < 105\%$ , in obvious contrast to the particles' intrinsic heterogeneous ice nucleation ability shown in part a where ice was only formed via the immersion freezing mode after droplet activation. As for CBV400, the ice-active fraction of the pre-activated aerosol particles decreases by about 50 % after warming the AIDA chamber from 250 to 253 K (part d).

## Appendix C: Ice nucleation experiments with diatomaceous earth

The intrinsic heterogeneous ice nucleation ability of the diatomaceous earth particles was probed at three different temperatures (Fig. C1a–c). The data from parts a and c underline the transition from poor ice nucleation ability at  $T > 237\text{ K}$  to extraordinarily high ice nucleation ability at  $T < 237\text{ K}$ . The unprocessed diatomaceous earth particles do not promote ice formation in the deposition mode in an expansion run started at 250 K (part a), and even after droplet activation (vertical line) the number concentration of ice crystals formed by immersion freezing is initially very small. Only upon further cooling to 241 K, the ice-active fraction gradually increases to about 1 %. In contrast, 80 % of the aerosol population is activated at a peak  $RH_{ice}$  value of only 107 % when the expansion run is started at 233 K (part c). A peculiarity of the ice nucleation behaviour of the diatomaceous earth particles is shown in part b of Fig. C1. Here, the intrinsic immersion freezing ability was probed at a slightly lower temperature than in the expansion run shown in part a. Droplet activation of the aerosol particles during expansion cooling occurs at a temperature of about 241 K (first vertical line), and upon further cooling to 239.5 K (second vertical line) the ice-active fraction of the immersed aerosol particles gradually increases to about 6 %. Thereafter, the droplet cloud completely glaciates within a short time period of only 20 s although the gas temperature was still about 2.5 K above the homogeneous freezing temperature. This indicates that the diatomaceous earth material features some ubiquitous surface properties that induce the freezing of supercooled water at a temperature higher than the homogeneous

Interactive Discussion

freezing threshold. A higher freezing temperature means that larger pores can be filled with ice by the PCF mechanism during temperature cycling (Fig. 5), as a result of which the pre-activation ability is retained to higher temperatures. An example of the ice nucleation ability of the pre-activated diatomaceous earth particles is given in Fig. C1d, showing that even at 256 K a dominant depositional ice growth mode with  $f_{\text{ice}} = 1\%$  can still be observed. Note that such behaviour could in principle also be expected for the illite NX particles due to their pronounced intrinsic heterogeneous ice nucleation ability above 237 K. The measurement data, however, reveal that the decrease of  $f_{\text{ice}}$  with increasing temperature is faster for illite NX compared to diatomaceous earth (Fig. 4). This might be due to the overall lack of larger void spaces in the clay mineral, meaning that such larger pores which could retain ice at higher temperatures are just not available.

### Appendix D: Ice nucleation experiments with GSG soot

GSG soot particles are an ideal candidate to probe the pre-activation efficiency because they are intrinsically even less ice-active than the CBV400 particles at  $T > 237\text{ K}$ . The expansion run with freshly injected GSG particles started at 246 K (Fig. D1a) discloses the absence of any ice formation in the deposition mode, and after droplet activation (first vertical line) only a minor nucleation mode due to immersion freezing with  $f_{\text{ice}} = 0.05\%$  can be observed after the gas temperature has dropped below 239 K. As shown by previous AIDA measurements, however, the GSG soot particles are very efficient deposition mode INPs below 237 K (Möhler et al., 2005), suggesting that the PCF mechanism becomes active for this kind of material as well. This is supported by our new experiments, showing that pre-activated GSG soot particles reveal a clear depositional ice growth mode when probed at 246 K after temporary cooling to 228 K (Fig. D1b). The ice-active fraction is rather small with only about 0.2%, and the pre-activation ability already disappears completely at temperatures above 250 K. This indicates that the void spaces in the soot aggregates are rather small so that the enclosed

Interactive Discussion

ice pockets have a low melting temperature. As already highlighted in our article, the pre-activation ability shown in part b is only observed when a fresh load of GSG soot particles is subjected to the temperature-cycling program. When the cloud-processed and thereby compacted particles from the experiment shown in part a are temporarily cooled to 228 K, their ice nucleation ability does not improve at 246 K.

## Appendix E: Ice nucleation experiments with SD2, ID, CID, and EY01

As emphasised in the discussion, pre-activation by the PCF mechanism at  $RH_{ice} < 100\%$  requires the formation of ice-filled pores during the temporary cooling cycle to 228 K. These ice-filled pores facilitate the depositional growth of macroscopic ice crystals after warming the pre-activated aerosol particles to temperatures in the range from 245 to 260 K where the pre-activation ability was tested in succeeding expansion cooling experiments. The pronounced intrinsic heterogeneous ice nucleation ability at very low supersaturation thresholds of the zeolite CBV400, illite NX, and diatomaceous earth particles at  $T < 237$  K can also be explained by the PCF mechanism. This observation indicates that the pores of the materials were already filled with ice before the start of the expansion cooling experiments, underlining the availability of pores in a size regime where water condensation can occur at relative humidities below ice saturation. Since the latter is the prerequisite for observing pre-activation at  $RH_{ice} < 100\%$ , we can use the intrinsic heterogeneous ice nucleation ability of a certain compound at  $T < 237$  K as a proxy to estimate whether it is prone to pre-activation or not.

In Fig. E1, we have compiled AIDA data for the intrinsic heterogeneous ice nucleation abilities of the SD2, ID, CID, and EY01 particles probed in expansion cooling experiments at  $T < 237$  K. The experiments with the ID and CID particles were conducted in the present study, whereas the data for SD2 and EY01 were taken from preceding measurement campaigns (Möhler et al., 2006; Steinke et al., 2011). The SD2, ID, and EY01 particles promote heterogeneous ice nucleation below water saturation, but the  $RH_{ice}$  threshold for the initiation of ice formation is in the range between 110 and 120 %, 29027

Interactive Discussion

which is clearly higher than for the CBV400, illite NX, and diatomaceous earth particles. Consequently, these samples were found not to be susceptible to pre-activation at  $RH_{ice} < 100\%$ , so that temperature cycling did not modify their intrinsic heterogeneous ice nucleation ability at temperatures between 245 and 260 K. In contrast, a small pre-activation mode due to depositional ice growth was observed for the CID particles (Fig. E2). Unprocessed CID particles were shown to be ice-active only in the immersion freezing mode for temperatures above 240 K (Kanji et al., 2011). After temperature cycling, however, macroscopic ice growth starts at  $RH_{ice} = 105\%$  (first vertical line in Fig. E2) when the particles are probed in an expansion cooling experiment at 250 K. In the later course of expansion cooling (second vertical line), the CID particles are activated to cloud droplets and additional ice crystals are formed due to the intrinsic immersion freezing ability of the material. The observation that the CID particles are prone to pre-activation manifests itself in their higher intrinsic heterogeneous ice nucleation ability at  $T < 237$  K compared to SD2, ID, and EY01 (Fig. E1c). Ice formation initiates at  $RH_{ice} = 103\%$  and 60 % of the aerosol population gets activated although the peak relative humidity with respect to ice is limited to 108 % during expansion cooling. Ice nucleation measurements for CID performed with a continuous flow diffusion chamber show much higher onset ice relative humidities at temperatures below 237 K compared to the AIDA where the dust particles are probed in situ after a longer residence time in a cold and humid environment (Koehler et al., 2010). This finding stimulates further research on the kinetics of the PCF mechanism because it could be important for the interpretation of ice nucleation efficiencies measured by INP counters at  $T < 237$  K.

## Pre-activation of ice nucleating particles

R. Wagner et al.

**Figure 3.** Ice nucleation characteristics of unprocessed (a and b) and pre-activated (c and d) zeolite particles (CBV400) during expansion cooling. Each part shows the relative humidity with respect to ice (black line), the chamber gas phase temperature (red line), the aerosol and cloud particle size distribution (dark-yellow dots), and the ice-active fraction of the aerosol population (blue line).

## Pre-activation of ice nucleating particles

R. Wagner et al.

**Figure 4.** Temperature-dependent ice-active fractions after pre-activation for different aerosol types in the depositional ice growth mode (filled bars) and the condensational ice growth mode (bars without colour filling). Exemplary error bars denote the uncertainty of  $\pm 20\%$  for  $f_{\text{ice}}$ . The estimated detection limit for  $f_{\text{ice}}$  is 0.04%. For the SD2, ID, EY01, and water-processed GSG soot particles, the pre-activation efficiency is below this limit.

Interactive Discussion

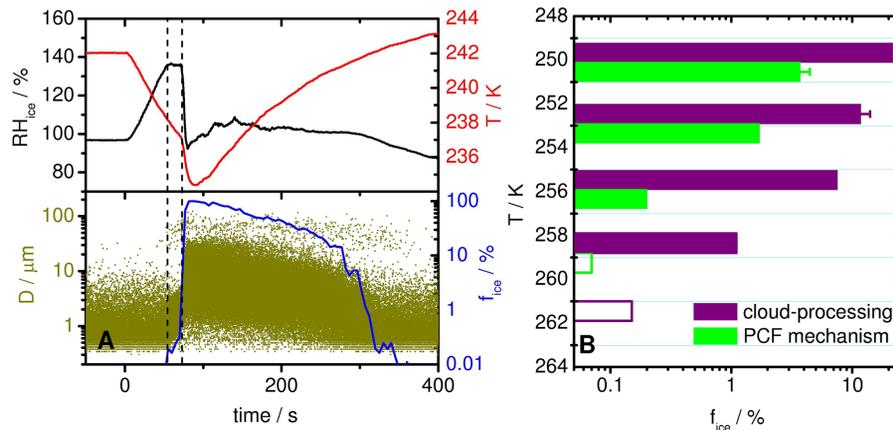

**Figure 5.** (a) Exemplary time series of the AIDA wall temperature for a pre-activation experiment with diatomaceous earth particles. The different stages of the experiment (blue squares) are explained in the text. The PCF mechanism is analysed in terms of the pore-size dependent onset  $RH_w$  of capillary condensation (b) and the ice freezing and melting temperatures (c). The pore condensation curves (b) were computed with the inverse Kelvin equation for 253 K (upper thick line) and 237 K (lower thick line), as well as for two intermediate temperatures (247 and 243 K, thin lines). The temperature-dependent pore ice stability curve (c) is derived from the critical embryo size for homogeneous ice nucleation as defined in Classical Nucleation Theory. Ice in pores is assumed to be stable only at pore diameters and temperatures below this line. See Sect. 4.1 for computational details.

## Pre-activation of ice nucleating particles

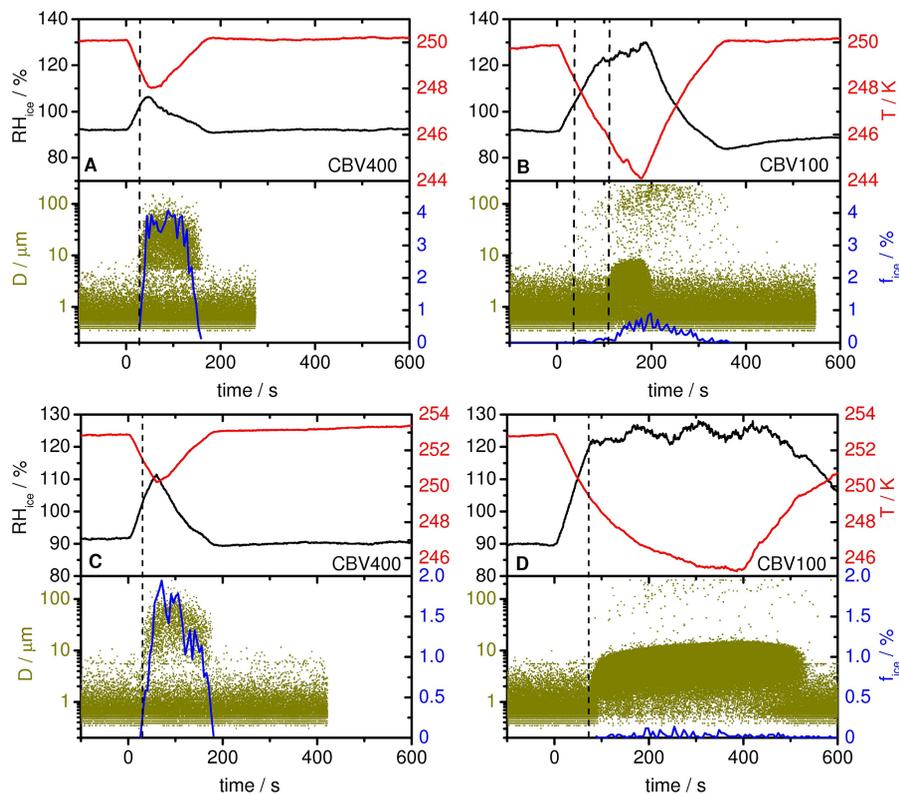

R. Wagner et al.

**Figure 6.** (a) AIDA expansion experiment with zeolite particles (CBV400), simulating aerosol-processing in deep convective clouds. The data types are the same as shown in Fig. 3. (b) Temperature-dependent ice-active fractions for CBV400 particles after pre-activation by the PCF mechanism (identical to those shown in Fig. 4) and by the cloud-processing mechanism (a).

## Pre-activation of ice nucleating particles

R. Wagner et al.

**Figure E1.** Comparison of the ice nucleation characteristics of unprocessed SD2 (a), ID (b), CID (c), and EY01 (d) particles during expansion cooling at temperatures below 237 K. The data types are the same as shown in Fig. 3. In the experiment with the SD2 particles, only the optical particle counter with the upper size threshold of 46  $\mu\text{m}$  was operated. This means that larger ice crystals were still appropriately counted but not correctly sized (i.e., classified to the size channel 46  $\mu\text{m}$ ).
