14 **Abstract**

15 The Arctic environment is undergoing rapid changes such as faster warming than the
16 global average and exceptional melting of glaciers in Greenland. Black carbon (BC) particles,
17 which are a short-lived climate pollutant, are one cause of Arctic warming and glacier
18 melting. However, the sources of BC particles are still uncertain. We simulated the potential
19 emission sensitivity of atmospheric BC present over the Arctic (north of 66° N) using the
20 Flexpart Lagrangian transport model (version 10.1). This version includes a new aerosol wet
21 removal scheme, which better represents particle-scavenging processes than older versions
22 did. Arctic BC at the surface (0–500 m) and high altitudes (4750–5250 m) is sensitive to
23 emissions in high latitude (north of 60° N) and mid-latitude (30–60° N) regions, respectively.
24 Geospatial sources of Arctic BC were quantified, with a focus on emissions from
25 anthropogenic activities and biomass burning in 2010. We found that anthropogenic sources
26 contributed 82 % and 83 % of annual Arctic BC at the surface and high altitudes,
27 respectively. Arctic surface BC comes predominantly from anthropogenic emissions in
28 Russia (56 %), with gas flaring from the Yamalo-Nenets Autonomous Okrug and Komi
29 Republic being the main source (31 % of Arctic surface BC). These results highlight the need
30 for regulations to control BC emissions from gas flaring to mitigate the rapid changes in the
31 Arctic environment. In summer, combined biomass burning in Siberia, Alaska, and Canada
32 contributes 56–85 % (75 % on average) and 40–72 % (57 %) of Arctic BC at the surface and
33 high altitudes, respectively. A large fraction (40 %) of BC in the Arctic at high altitudes comes
34 from anthropogenic emissions in East Asia, which suggests that the rapidly growing
35 economies of developing countries could have a non-negligible effect on the Arctic. To our
36 knowledge, this is the first year-round evaluation of Arctic BC sources that has been

37 performed using the new wet deposition scheme in Flexpart. The study provides a scientific

38 basis for actions to mitigate the rapidly changing Arctic environment.

39

40 **1 Introduction**

41 The Arctic region has experienced warming at a rate twice that of the global average in
42 recent decades (Cohen et al., 2014). The Arctic cryosphere has been undergoing
43 unprecedented changes since the mid-1800s (Trusel et al., 2018). Glacier cover in Greenland
44 reached its historically lowest level in summer 2012 (Tilling et al., 2015). Evidence indicates
45 that the emissions and transport of greenhouse gases and aerosols to the Arctic region are
46 contributing to such warming and melting of snow and ice (Keegan et al., 2014; Najafi et al.,
47 2015). Short-lived climate pollutants such as black carbon (BC) particles, tropospheric ozone,
48 and methane greatly affect the Arctic climate (AMAP, 2015; Quinn et al., 2008).

49 BC particles are emitted during incomplete combustion of fossil fuels, biofuels, and
50 biomass. BC warms the atmosphere by direct absorption of solar radiation. The deposition
51 of BC on snow and ice surfaces accelerates their melting through decreasing albedo, which
52 contributes to the rapid loss of glaciers. In the Arctic region, ground-based observations
53 have indicated that BC shows clear seasonal variations, with elevated mass concentrations
54 in winter and spring (the so-called Arctic haze) and low values in summer (Law and Stohl,
55 2007). Such seasonal variations are explained by increased transport from lower latitudes in
56 the cold season and increased wet scavenging in the warm season (Shaw, 1995; Garrett et
57 al., 2011; Shen et al., 2017).

58 The presence of BC particles in the Arctic is mainly attributed to emissions in high-latitude
59 regions outside the Arctic, such as northern Europe and Russia (Stohl, 2006; Brock et al.,
60 2011). This is partly caused by the polar dome (Stohl, 2006), which is formed because of the
61 presence of constant potential temperature near the surface. The emissions in high-latitude
62 regions are transported to the Arctic region and trapped in the dome, which increases the
63 surface concentration. Recently, Schmale et al. (2018) suggested that local emissions from

64 within the Arctic are another important source, and these are expected to increase in the
65 future.

66 Although numerous studies have been performed, results regarding regional
67 contributions of BC sources in the Arctic are still inconclusive. For example, ground-based
68 observations and Lagrangian transport model results reported by Winiger et al. (2016)
69 showed that BC in Arctic Scandinavia is predominantly linked to emissions in Europe. Over
70 the whole Arctic region (north of 66° N), Russia contributes 62 % to surface BC in terms of
71 the annual mean (Ikeda et al., 2017). Gas flaring in Russia has been identified as a major
72 (42 %) source of BC at the Arctic surface (Stohl et al., 2013). Xu et al. (2017) found that
73 anthropogenic emissions from northern Asia contribute 40–45 % of Arctic surface BC in
74 winter and spring. However, the results of some other studies have suggested that Russia,
75 Europe, and South Asia each contribute 20–25 % of BC to the low-altitude springtime Arctic
76 haze (Koch and Hansen, 2005). Sand et al. (2016) found that the surface temperature in the
77 Arctic is most sensitive to emissions in Arctic countries, and Asian countries contribute
78 greatly to Arctic warming because of the large absolute amount of emissions.

79 Various models have been used to investigate BC sources in the Arctic. Depending on the
80 simulation method, these models are generally categorized as Lagrangian transport models
81 (Hirdman et al., 2010; Liu et al., 2015; Stohl et al., 2006, 2013), chemical transport models
82 (Ikeda et al., 2017; Koch and Hansen, 2005; Qi et al., 2017; Shindell et al., 2008; Wang et al.,
83 2011; Xu et al., 2017), and global climate models (Ma et al., 2013; Schacht et al., 2019; H.
84 Wang et al., 2014). The uncertainties of the simulations are mainly generated from the
85 model treatment of processes for BC particle removal, especially wet-scavenging processes
86 (Kipling et al., 2013; Schacht et al., 2019; Q. Wang et al., 2014). The use of emission
87 inventories is another important factor that affects the simulation results (Dong et al.,

88 2019). The observations of BC that are used for model comparisons may be biased by 30 %
89 depending on the method used (Sinha et al., 2017; Sharma et al., 2017). There are still large
90 uncertainties regarding the sources of BC in the Arctic with respect to emission sectors
91 (anthropogenic sources and biomass burning) and geospatial contributions (Eckhardt et al.,
92 2015).

93 In this study, we quantified region-separated sources of BC in the Arctic in 2010 by using
94 version 10.1 of the FLEXible PARTicle dispersion model (Flexpart) (Stohl et al., 1998, 2006,
95 2013; Grythe et al., 2017). We first evaluated the model performance by comparing the
96 results with those based on observations at surface sites. The source contributions of
97 emission sectors and geospatial contributions were evaluated by incorporating the Arctic BC
98 footprint into the emission inventories.

99 **2 Materials and methods**

100 2.1 Transport model

101 The Flexpart model (version 10.1) was run in backward mode to simulate BC footprints in
102 the Arctic region. The calculation of wet deposition was improved compared with those in
103 previous versions because in-cloud scavenging and below-cloud scavenging of particles were
104 separately calculated (Grythe et al., 2017). In previous versions of Flexpart, in the in-cloud
105 scavenging scheme, the aerosol scavenging coefficient depended on the cloud water
106 content, which was calculated according to an empirical relationship with precipitation rate,
107 in which all aerosols had the same nucleation efficiency (Hertel et al., 1995 ; Stohl et al.,
108 2005). In the new version, the in-cloud scavenging scheme depends on the cloud water
109 phase (liquid, ice, or mixed phase). Aerosols were set as ice nuclei for ice clouds and as
110 cloud condensation nuclei for liquid-water clouds, respectively. For mixed-phase clouds, it
111 was assumed that 10 % of aerosols are ice nuclei and 90 % are cloud condensation nuclei,

112 because BC is much more efficiently removed in liquid water clouds than in ice clouds (Cozic
113 et al., 2007; Grythe et al., 2017). The below-cloud scavenging scheme can parameterize
114 below-cloud removal as a function of aerosol particle size, and precipitation type (snow or
115 rain) and intensity. The biases produced in simulations using the new scheme are therefore
116 smaller than those in the old scheme for wet deposition of aerosols, especially at high
117 latitudes (Grythe et al., 2017).

118 The Arctic region is defined as areas north of 66° N. The potential BC emission
119 sensitivities at two heights in the Arctic region, i.e., the surface (0–500 m) and 5000 m
120 (4750–5250 m), were simulated. The Flexpart outputs were set as gridded retention times.
121 We performed tests at 500, 2000, and 5000 m, and chose 500 m as the upper boundary
122 height of the model output. The model was driven with operational analytical data from the
123 European Centre for Medium-Range Weather Forecasts (ECMWF) at a spatial resolution of
124 1° × 1° with 61 vertical levels. Temporally, ECMWF has a resolution of 3 h, with 6 h analysis
125 and 3 h forecast time steps. The simulation period was set at 60 days backward starting
126 from each month in 2010. The maximum life time of BC was set at 20 days because its
127 suspension time in the upper atmosphere during long-range transport is longer than that at
128 the surface level (Stohl et al., 2013). We implemented the wet deposition scheme in the
129 backward calculations, but it was not represented in the default setting (Flexpart v10.1,
130 <https://www.flexpart.eu/downloads>, obtained 10 April 2017).

131 The chemistry and microphysics could not be resolved by Flexpart. The model therefore
132 ignores hydrophobic to hydrophilic state changes and size changes of BC, and assumes that
133 all BC particles are aged hydrophilic particles. A logarithmic size distribution of BC with a
134 mean diameter of 0.16 μm and a standard deviation of 1.96, in accordance with our ship
135 observations in the Arctic, was used (Taketani et al., 2016). The particle density was

136 assumed to be 2000 kg m^{-3} , and 1 million computational particles were randomly generated
137 in the Arctic region for the backward runs.

138 Four ground-based observations made during the period 2007–2011 were used to
139 validate the model performance. The potential BC emission sensitivity at 0–500 m above
140 ground level from a 0.1° grid centered at each site was simulated. Other model
141 parameterizations were consistent with those for the Arctic region, except that 200 000
142 computational particles were released.

143 2.2 Emission inventories

144 We focused on BC sources from anthropogenic emissions and biomass burning. The
145 Hemispheric Transport of Air Pollution version 2 inventory (HTAP2) for 2010 was used for
146 anthropogenic emissions (Janssens-Maenhout et al., 2015). However, as it has been
147 reported that BC emissions in Russia were underestimated in HTAP2, we used the BC
148 emissions reported by Huang et al. (2015) for Russia, in which the annual BC emissions were
149 224 Gg yr^{-1} . For biomass burning, we used the Global Fire Emissions Database version 3
150 inventory (GFED3) (van der Werf et al., 2010) for the purposes of intercomparison with
151 other studies, as this version is widely used. Geospatial distributions of emissions from
152 anthropogenic sources and biomass burning in January and July are shown in Fig. S1.

153 2.3 Calculation of Arctic BC source contributions

154 The source contributions to Arctic BC were derived by incorporating the gridded
155 retention time into the column emission flux, which was derived from the emission
156 inventories in each grid. Calculations for anthropogenic sources and biomass burning were
157 performed separately and the sum was used. For anthropogenic sources, the regions were
158 separated into North America and Canada ($25\text{--}80^\circ \text{ N}$, $50\text{--}170^\circ \text{ W}$), Europe ($30\text{--}80^\circ \text{ N}$, $0\text{--}30^\circ$
159 E), Russia ($53\text{--}80^\circ \text{ N}$, $30\text{--}180^\circ \text{ E}$), East Asia ($35\text{--}53^\circ \text{ N}$, $75\text{--}150^\circ \text{ E}$ and $20\text{--}35^\circ \text{ N}$, $100\text{--}150^\circ \text{ E}$),

160 and others (the rest) (Fig. 1a). For biomass-burning sources, the regions were separated into
161 Alaska and Canada (50–75° N, 50–170° W), Siberia (50–75° N, 60–180° E), and others (Fig.
162 1b).

163 **3 Results and discussion**

164 **3.1. Comparisons of simulations with BC observations at Arctic surface sites**

165 BC levels simulated by Flexpart were compared with those based on surface observations
166 at four sites: Barrow, USA (156.6° W, 71.3° N, 11 m asl), Alert, Canada (62.3° W, 82.5° N,
167 210 m asl), Zeppelin, Norway (11.9° E, 78.9° N, 478 m asl), and Tiksi, Russia (128.9° E, 71.6°
168 N, 8 m asl). Aerosol light absorption was determined by using particle soot absorption
169 photometers (PSAPs) at Barrow, Alert, and Zeppelin, and an aethalometer at Tiksi. For PSAP
170 measurements, the equivalent BC values were derived using a mass absorption efficiency of
171 $10 \text{ m}^2 \text{ g}^{-1}$. The equivalent BC at Tiksi, which was determined with an aethalometer, was
172 obtained directly. These measurement data were obtained from the European Monitoring
173 and Evaluation Programme and World Data Centre for Aerosols database
174 (<http://ebas.nilu.no>).

175 It is worth noting that uncertainties could be introduced by using different BC
176 measurement techniques. An evaluation of three methods for measuring BC at Alert,
177 Canada indicated that an average of the refractory BC determined with a single-particle soot
178 photometer (SP2) and elemental carbon (EC) determined from filter samples give the best
179 estimate of BC mass (Sharma et al., 2017). Xu et al. (2017) reported that the equivalent BC
180 determined with a PSAP was close to the average of the values for refractory BC and EC at
181 Alert. In this study, we consider that the equivalent BC values determined with a PSAP at
182 Barrow, Alert, and Zeppelin to be the best estimate. There may be uncertainties in the
183 equivalent BC observations performed with an aethalometer at Tiksi because of co-existing

184 particles such as light-absorptive organic aerosols, scattering particles, and dusts
185 (Kirchstetter et al., 2004; Lack and Langridge, 2013). Interference by the filter and
186 uncertainties in the mass absorption cross section could also contribute to the bias
187 observed in measurements made with an aethalometer at Tiksi.

188 Flexpart generally reproduced the seasonal variations in BC at four Arctic sites well (Fig.
189 2). Winter maxima and summer minima were observed [Pearson correlation coefficient (R) =
190 0.53–0.80, root-mean-square error (RMSE) = 15.1–56.8 ng m⁻³]. This seasonality is probably
191 related to relatively stronger transport to the Arctic region in winter, accompanied by lower
192 BC aging and inefficient removal, as simulated by older versions of Flexpart (Eckhardt et al.,
193 2015; Stohl et al., 2013). In the older versions of Flexpart, in which clouds were
194 parameterized based on relative humidity, clouds frequently extended to the surface and at
195 times no clouds could be found in grid cells, with unrealistic precipitation (Grythe et al.,
196 2017). In comparison, in Flexpart v10.1, in which cloud is differentiated into liquid, solid, and
197 mixed phase, the cloud distribution is more consistent with the precipitation data. This
198 improvement in the cloud distribution and phase leads to a more realistic distribution of
199 below-cloud and in-cloud scavenging events.

200 Flexpart v10.1 underestimated observed BC in January to May at Barrow and Alert, and in
201 most months at Tiksi. This is probably related to the emission inventory used, although
202 seasonal variations in residential heating are included in HTAP2, which would reduce the
203 simulation bias (Xu et al., 2017). Simulations by GEOS-Chem using the same emission
204 inventories also underestimated BC levels at Barrow and Alert (Ikeda et al., 2017; Xu et al.,
205 2017). At Zeppelin, the Flexpart-simulated BC was higher than the observed value, especially
206 in winter. It has been reported that riming in mixed-phase clouds occurs frequently at
207 Zeppelin (Qi et al., 2017). During the riming process, BC particles act as ice particles and

208 collide with the relatively numerous water drops, which form frozen cloud droplets, and
209 then snow is precipitated. This results in relatively efficient BC scavenging (Hegg et al.,
210 2011). Such a process could not be dealt with by the model.

211 Anthropogenic emissions are the main sources of BC at the four Arctic sites from late
212 autumn to spring, whereas biomass-burning emissions make large contributions in summer.
213 From October to April, anthropogenic emissions accounted for 87–100 % of BC sources at all
214 the observation sites. At Barrow, biomass burning accounted for 54–86 % of BC in June–
215 September (Fig. 2a). It was reported that observed high values of BC were unintentionally
216 excluded by local pollution data screening from the data set for Barrow in the forest fire
217 season in summer (Stohl et al., 2013); the notably higher level of simulated BC may reflect
218 this. There are large interannual variations in both observed and simulated BC (Fig. S2). In
219 June–August 2010, the mean contributions of biomass burning to BC were ~9.8, 6.3, 2.4,
220 and 8.6 times those from anthropogenic sources at Barrow, Alert, Zeppelin, and Tiksi,
221 respectively. In this study, we focused on BC in the Arctic region in 2010.

222 **3.2 Potential emission sensitivity of Arctic BC**

223 The potential emission sensitivities (footprint) of Arctic BC showed different patterns
224 with respect to altitude. The Arctic surface is sensitive to emissions at high latitudes (>60°
225 N). Air masses stayed for over 60 s in each of the 1° grids from the eastern part of northern
226 Eurasia and the Arctic Ocean before being transported to the Arctic surface in the winter,
227 represented by January (Fig. 3a). In comparison, during the summer, represented by July, BC
228 at the Arctic surface was mainly affected by air masses that originated from the Arctic
229 Ocean and the Norwegian Sea (Fig. 3b). These results imply that local BC emissions within
230 the Arctic regions, although relatively weak compared with those from the mid-latitude
231 regions, could strongly affect Arctic air pollution. Local BC emissions are important in the

232 wintertime because the relatively stable boundary layer does not favor pollution dispersion.
233 Recent increases in anthropogenic emissions in the Arctic region, which have been caused
234 by the petroleum industry and development of the Northern Sea Route, are expected to
235 cause deterioration of air quality in the Arctic. Socio-economic developments in the Arctic
236 region would increase local BC emissions, and this will be a non-negligible issue in the future
237 (Roiger et al., 2015; Schmale et al., 2018).

238 BC at high altitudes (~ 5000 m) in the Arctic is more sensitive to mid-latitude ($30\text{--}60^\circ$ N)
239 emissions, especially in wintertime. In January, air masses hovered over the Bering Sea and
240 the North Atlantic Ocean before arriving at the Arctic (Fig. 3c). A notable corridor at $30\text{--}50^\circ$
241 N covering Eurasia and the United States was the sensitive region that affected BC at high
242 altitudes in the Arctic in January. These results indicate that mid-latitude emissions,
243 especially those with relatively large strengths from East Asia, East America, and Europe,
244 could alter the atmospheric constituents at high altitudes in the Arctic. Central to east
245 Siberia was the most sensitive region for BC at high altitudes in the Arctic in July (Fig. 3d).
246 These results suggest that pollutants from frequent and extensive wildfires in Siberia in
247 summer are readily transported to high altitudes in the Arctic. Boreal fires are expected to
248 occur more frequently and over larger burning areas under future warming (Veira et al.,
249 2016), therefore the atmospheric constituents and climate in the Arctic could undergo more
250 rapid changes.

251 **3.3 Seasonal variations and sources of Arctic surface BC**

252 Arctic surface BC showed clear seasonal variations, with a primary peak in winter–spring
253 (December–March, $61.8\text{--}82.8$ ng m $^{-3}$) and a secondary peak in summer (July, 52.7 ng m $^{-3}$).
254 BC levels were relatively low in May–June ($21.8\text{--}23.1$ ng m $^{-3}$) and September–November
255 ($34.1\text{--}40.9$ ng m $^{-3}$) (Fig. 4a). This seasonality is in agreement with observations and

256 simulations at Arctic sites (Barrow, Alert, and Tiksi) (Stohl et al., 2013), and previous studies
257 targeting the whole Arctic (Ikeda et al., 2017; Xu et al., 2017). Compared with the study
258 reported by Stohl et al. (2013), the current work using the new scheme produced smaller
259 discrepancies between the simulated data and observations. Although the simulation
260 periods (monthly means for 2007–2011 in this study and for 2008–2010 in the old scheme)
261 and the anthropogenic emission inventories (HTAP2 in this study and ECLIPSE4 in the
262 previous study) are different, the new scheme shows potential for better representing BC
263 transport and removal processes in the Arctic.

264 The annual mean Arctic BC at the surface was estimated to be 48.2 ng m^{-3} . From October
265 to April, anthropogenic sources accounted for 96–100 % of total BC at the Arctic surface.
266 Specifically, anthropogenic emissions from Russia accounted for 61–76 % of total BC in
267 October–May (56 % annually), and was the dominant sources of Arctic BC at the surface.
268 From an isentropic perspective, the meteorological conditions in winter favored the
269 transport of pollutants from northern Eurasia to the lower Arctic, along with diabatic cooling
270 and strong inversions (Klonecki et al., 2003). In comparison, biomass burning from boreal
271 regions accounted for 56–85 % (75 % on average) of Arctic BC at the surface in summer;
272 biomass-burning emissions from North America and Canada accounted for 54 % of total
273 Arctic surface BC in June, and those from Siberia accounted for 59–61 % in July–August.
274 Wildfires in the boreal forests in summer had a major effect on air quality in the Arctic. On
275 an annual basis, anthropogenic sources and biomass-burning emissions accounted for 82 %
276 and 18 %, respectively, of total Arctic surface BC. In comparison, a recent study based on
277 isotope observations at the Arctic sites and a Flexpart model simulation suggested that
278 biomass burning contributed 39 % of annual BC in 2011–2015 (Winiger et al., 2019).

279 The geospatial contributions of anthropogenic sources and biomass-burning emissions
280 can be further illustrated by taking January and July as examples. In January, high levels of
281 anthropogenic emissions from Russia (contributing 64 % of Arctic surface BC), Europe
282 (18 %), and East Asia (9 %) were identified (Fig. 5a). Specifically, Yamalo-Nenets
283 Autonomous Okrug in Russia, which has the largest reserves of Russia's natural gas and oil
284 (Filimonova et al., 2018), was the most notable emission hotspot, which suggests gas-flaring
285 sources. The Komi Republic in Russia was also identified as a strong anthropogenic emitter
286 contributing to Arctic surface BC. These gas-flaring industrial regions in Russia (58–69° N,
287 68–81°E) together contributed 33 % and 31 % of Arctic surface BC for January and the
288 annual mean, respectively. Recently, Dong et al. (2019) evaluated BC emission inventories
289 using GEOS-Chem and proposed that using the inventory compiled by Huang et al. (2015)
290 for Russia, in which gas flaring accounted for 36 % of anthropogenic emissions, had no
291 prominent impact on the simulation performance in Russia and the Arctic. They suggested
292 that use of a new global inventory for BC emissions from natural gas flaring would improve
293 the model performance (Huang and Fu, 2016). These results suggest that inclusion of BC
294 emissions from gas flaring on the global scale is necessary for further BC simulations.

295 In Europe, a relatively high contribution of anthropogenic emissions to Arctic surface BC
296 in January was made by Poland (50–55° N, 15–24° E, contributing 4 % of Arctic surface BC)
297 because of relatively large emission fluxes in the region (Fig. S1a). Anthropogenic emissions
298 from East China, especially those north of ~33° N (33–43° N, 109–126° E), contributed
299 perceptibly (5 %) to Arctic surface BC.

300 In July, contributions from anthropogenic sources shrank to those from Yamalo-Nenets
301 Autonomous Okrug and Komi Republic in Russia, and contributed a lower fraction (3 % of
302 Arctic surface BC) (Fig. 5b). Few biomass-burning sources contributed in January (Fig. 5c),

303 but contributions from biomass burning to Arctic surface BC in July can be clearly seen,
304 mainly from the far east of Russia, Canada, and Alaska (Fig. 5d). Biomass burning emissions
305 from Kazakhstan, southwest Russia, southern Siberia, and northeast China also contributed
306 to Arctic surface BC, although at relatively low strengths (Fig. 5d and Fig. S1d). However, the
307 contributions from biomass burning could be higher, as the MODIS burned area, the basis of
308 GFED emission inventories, was underestimated for northern Eurasia by 16 % (Zhu et al.,
309 2017). Evangeliou et al. (2016) estimated a relatively high transport efficiency of BC from
310 biomass-burning emissions to the Arctic, which led to a high contribution, i.e., 60 %, from
311 such sources to BC deposition in the Arctic in 2010. A recent study suggested that open fires
312 burned in western Greenland in summer (31 July to 21 August 2017) could potentially alter
313 the Arctic air composition and foster glacier melting (Evangeliou et al., 2019). Although the
314 footprint of Arctic surface BC showed a relatively weak sensitivity to areas such as forests
315 and tundra, in the boreal regions, pollutants from boreal wildfires could have greater effects
316 on the Arctic air composition in summer under future warming scenarios (Veira et al., 2016).

317 **3.4 Sources of Arctic BC at high altitudes**

318 Arctic BC levels at high altitudes (4750–4250 m) showed the highest levels in spring
319 (March–April, 40.5–53.9 ng m⁻³), followed by those in late autumn to early winter
320 (November–January, 36.5–40.0 ng m⁻³), and summer (July–August, 33.0–39.0 ng m⁻³) (Fig.
321 4). The annual mean Arctic BC at high altitudes was estimated to be 35.2 ng m⁻³, which is ca.
322 73 % of those at the surface. Such a vertical profile is in accordance with those based on
323 aircraft measurements over the High Canadian Arctic (Schulz et al., 2019). Similarly to the
324 case for the surface, anthropogenic sources accounted for 94–100 % of Arctic BC at high
325 altitudes in October–May. East Asia accounted for 34–65 % of the total BC in October–May
326 (40 % annually). In comparison, using the Community Atmosphere Model version 5 driven

327 by the NASA Modern Era Retrospective-Analysis for Research and Applications reanalysis
328 data and the IPCC AR5 year 2000 BC emission inventory, H. Wang et al. (2014) found that
329 East Asia accounted for 23% of BC burden in the Arctic for 1995–2005. In summer, biomass
330 burning in the boreal regions accounted for 40–72 % (57 % on average) of Arctic BC at high
331 altitudes, similar to the source contributions to Arctic surface BC. Specifically, biomass-
332 burning sources from Siberia accounted for 40–42 % of Arctic BC at high altitudes in July–
333 August. Annually, anthropogenic sources and biomass burning accounted for 83 % and 17 %,
334 respectively, of total Arctic BC at high altitudes.

335 Further investigations of geospatial contributions to Arctic BC at high altitudes in January
336 and July provided more details regarding BC sources. In January, the main anthropogenic BC
337 source in East Asia covered a wide range in China (Fig. 5a). Not only east and northeast
338 China, but also southwest China (Sichuan and Guizhou provinces) were the major
339 anthropogenic sources of Arctic BC at high altitudes. In July, anthropogenic sources made a
340 relatively weak contribution to Arctic BC at high altitudes. The regions that were sources of
341 biomass-burning contributions to Arctic BC at high altitudes were mainly the far east of
342 Siberia, Kazakhstan, central Canada, and Alaska, i.e., similar to the sources of Arctic surface
343 BC. Unlike Arctic surface BC, for which the dominant source regions are at high latitudes in
344 both winter and summer, Arctic BC at high altitudes mainly originates from mid-latitude
345 regions (Figs. 5 and 6). In terms of transport pathways, air masses could be uplifted at low-
346 to-mid latitudes and transported to the Arctic (Stohl, 2006). Further investigations are
347 needed to obtain more details of the transport processes.

348 **3.5 Comparison of Flexpart and GEOS-Chem simulations of BC sources**

349 Data for BC sources simulated with Flexpart were compared with those obtained with
350 GEOS-Chem (Ikeda et al., 2017), which is an Eulerian atmospheric transport model, using the

351 same emission inventories. The simulated seasonal variations in Arctic BC levels and source
352 contributions obtained with Flexpart agreed well with those obtained with GEOS-Chem (Fig.
353 S3). The annual mean BC levels at the Arctic surface obtained by Flexpart and GEOS-Chem
354 simulations were 48 and 70 ng m⁻³, respectively; the high-altitude values simulated by
355 Flexpart and GEOS-Chem were 35 and 38 ng m⁻³, respectively. The magnitude difference
356 between the BC levels at the Arctic surface could be related to meteorology. ECMWF ERA-
357 Interim data were used as the input for the Flexpart simulation, whereas the GEOS-Chem
358 simulation was driven by assimilated meteorological data from the Goddard Earth
359 Observation System (GEOS-5).

360 The treatments of the BC removal processes could also lead to different simulation
361 results, depending on the model. In terms of BC loss processes, dry and wet depositions
362 were the removal pathways, depending on the particle size and density, in Flexpart. The
363 treatment of meteorology, especially cloud water and precipitation, would therefore affect
364 the uncertainties of the simulations. In Flexpart version 10.1, BC particles are separately
365 parameterized as ice nuclei for ice clouds, cloud condensation nuclei for liquid-water clouds,
366 and 90 % as cloud condensation nuclei for mixed-phase clouds. The separation of mixed-
367 phase clouds is realistic, as 77 % of in-cloud scavenging processes occurred in the mixed
368 phase over a 90 day period starting from December 2006 (Grythe et al., 2017).

369 In GEOS-Chem simulations, the BC aging was parameterized based on the number
370 concentration of OH radicals (Liu et al., 2011). The BC was assumed to be hydrophilic in
371 liquid clouds ($T \geq 258$ K) and hydrophobic when serving as ice nuclei in ice clouds ($T < 258$ K)
372 (Wang et al., 2011), with modifications because the scavenging rate of hydrophobic BC was
373 reduced to 5 % of water-soluble aerosols for liquid clouds (Bourgeois and Bey, 2011). Such a
374 treatment is expected to improve the simulation accuracy (Ikeda et al., 2017).

375 In Lagrangian models, the trajectories of particles are computed by following the
376 movement of air masses with no numerical diffusion, although some artificial numerical
377 errors could be generated from stochastic differential equations (Ramli and Esler, 2016). As
378 a result, long-range transport processes can be well simulated (Stohl, 2006; Stohl et al.,
379 2013). In comparison, Eulerian chemical transport models such as GEOS-Chem have the
380 advantage of simulating non-linear processes on the global scale, which enables treatment
381 of the BC aging processes (coating with soluble components) (Bey et al, 2001; Eastham et
382 al., 2018). However, with GEOS-Chem, the capture of intercontinental pollution plumes is
383 difficult because of numerical plume dissipation (Rastigejev et al., 2010). Nevertheless, the
384 agreement between the Flexpart and GEO-Chem simulations of BC source contributions
385 indicates improved reliability of evaluated source contributions to Arctic BC.

386 **4 Conclusions**

387 The source contributions to Arctic BC were investigated by using a Flexpart (version 10.1)
388 transport model that incorporated emission inventories. Flexpart-simulated BC data agreed
389 well with observations at Arctic sites, i.e., Barrow, Alert, Zeppelin, and Tiksi. The source
390 regions and source sectors of BC at the surface and high altitudes (~ 5000 m) over a wide
391 region in the Arctic north of 66° N were simulated. BC at the Arctic surface was sensitive to
392 local emissions and those from nearby Nordic countries (>60° N). These results emphasize
393 the role of anthropogenic emissions such as gas flaring and development of the Northern
394 Sea Route in affecting air quality and climate change in the Arctic. Anthropogenic emissions
395 in the northern regions of Russia were the main source (56 %) of Arctic surface BC annually.
396 In contrast, BC in the Arctic at high altitudes was sensitive to mid-latitude emissions (30–60°
397 N). Although they are geospatially far from the Arctic, anthropogenic emissions in East Asia
398 made a notable (40 %) contribution to BC in the Arctic at high altitudes annually. Biomass-

399 burning emissions, which were mainly from Siberia, Alaska, and Canada, were important in
400 summer, contributing 56–85 % of BC at the Arctic surface, and 40–72 % at Arctic high
401 altitudes. Future increases in wildfires as a result of global warming could therefore increase
402 the air pollution level during the Arctic summer. This study clarifies the source regions and
403 sectors of BC in the Arctic. This information is fundamental for understanding and tackling
404 air pollution and climate change in the region.

405
406 *Data Availability.* The data set for simulated footprint and BC source contributions is
407 available on request to the corresponding author.

408
409 *Author contributions.* CZ and YK designed the study. CZ, MT, and IP optimized the Flexpart
410 model. CZ performed Flexpart model simulations, conducted analyses, and wrote the
411 manuscript. KI and HT provided data for GEOS-Chem simulations and site observations. All
412 authors made comments that improved the paper.

413
414 *Competing interests.* The authors declare that they have no conflict of interest.

415 *Financial Support.* This study was supported by the Environmental Research and Technology
416 Development Fund (2-1505) of the Ministry of the Environment, Japan.

417
418 *Acknowledgment.* We thank Helen McPherson, PhD, from Edanz Group
419 (www.edanzediting.com/ac) for editing a draft of this manuscript.

672

673 Figure 1. Regional separation for quantification of BC in the Arctic from (a) anthropogenic

674 and (b) biomass-burning sources.

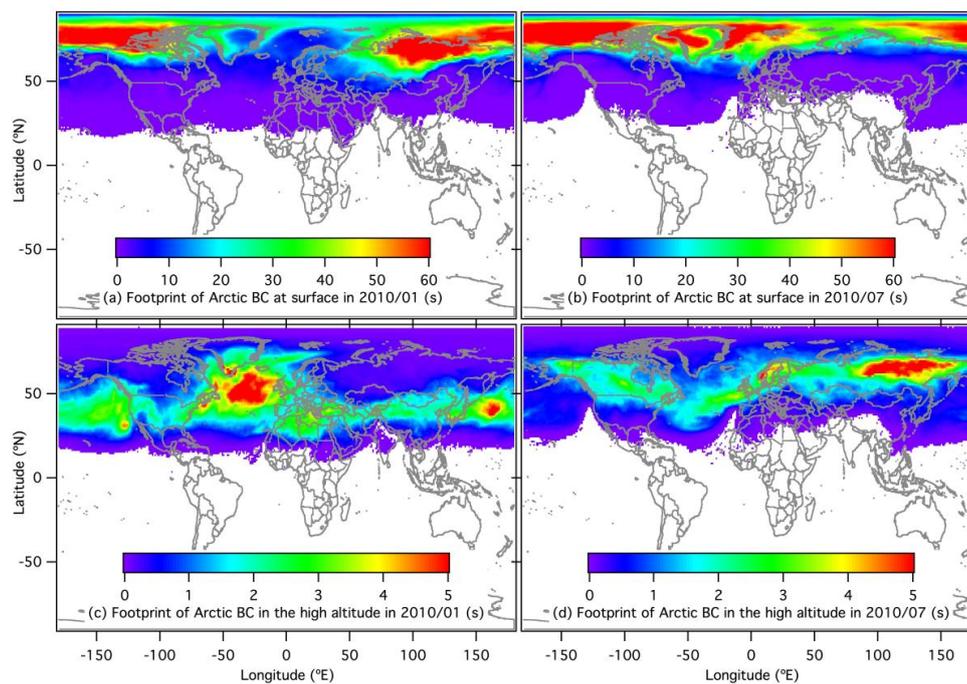

675

676

677 Figure 2. Observed (filled circles) and modeled (bars) seasonal variations in BC mass
678 concentrations at Arctic sites. Contributions from anthropogenic sources (blue) and biomass
679 burning (red) in each month are shown. Monthly averages of observed (filled circles) and
680 simulated (bars) BC were conducted for 2007–2011 at Barrow, USA (156.6° W, 71.3° N),
681 Alert, Canada (62.3° W, 82.5° N), and Zeppelin, Norway (11.9° E, 78.9° N), and for 2010–
682 2014 at Tiksi, Russia (128.9° E, 71.6° N). *R* and RMSE indicate correlation coefficient and
683 root-mean-square error (ng m⁻³), respectively.

684

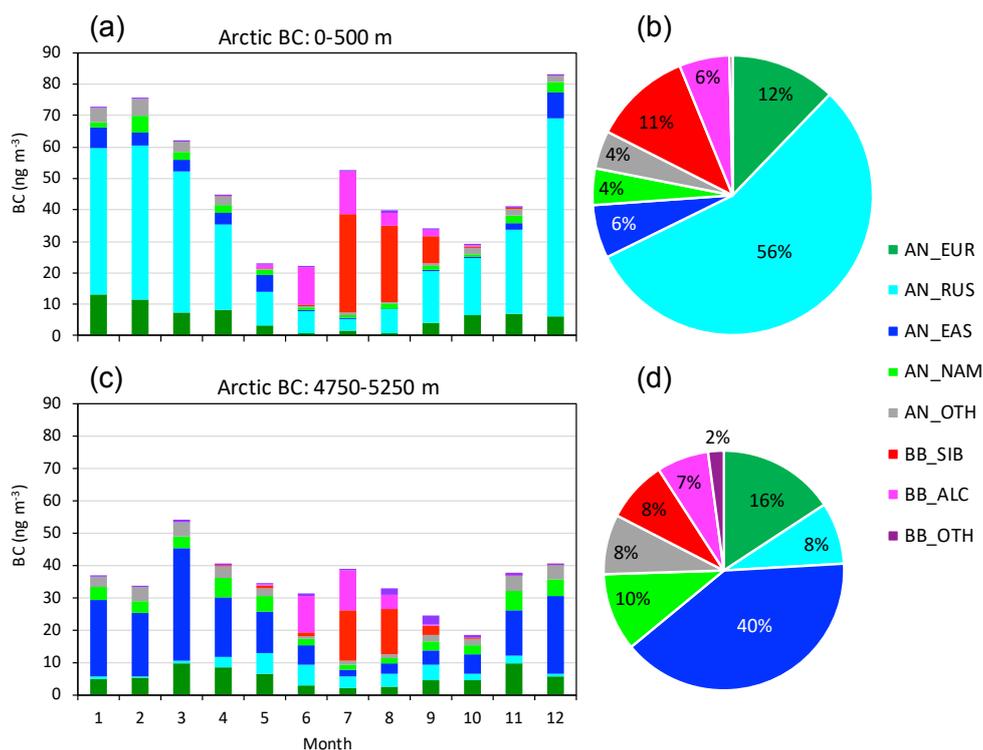

685

686 Figure 3. Footprints of Arctic BC shown as retention time(s) of (a) BC at surface (0–500 m) in

687 January 2010, (b) BC at surface in July 2010, (c) BC at high altitudes (4750–5250 m) in

688 January 2010, and (d) BC at high altitudes (4750–5250 m) in July 2010.

689

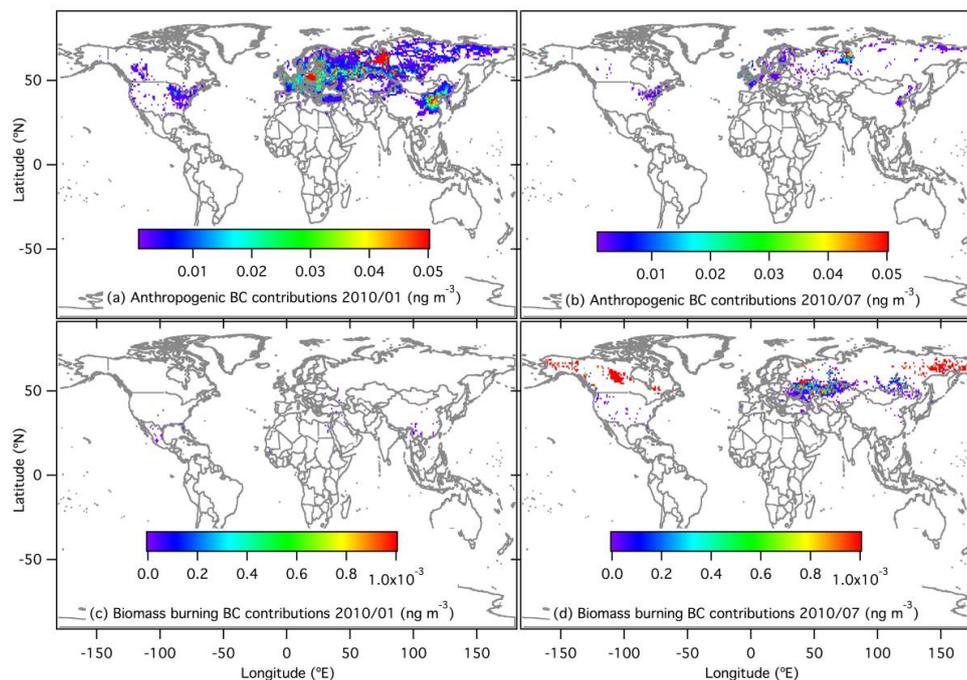

690

691 Figure 4. Contributions of anthropogenic sources and biomass burning from each region to

692 (a) seasonal variations in Arctic surface BC, (b) annual mean Arctic surface BC, (c) seasonal

693 variations in Arctic BC at high altitudes, and (d) annual mean of Arctic BC at high altitudes.

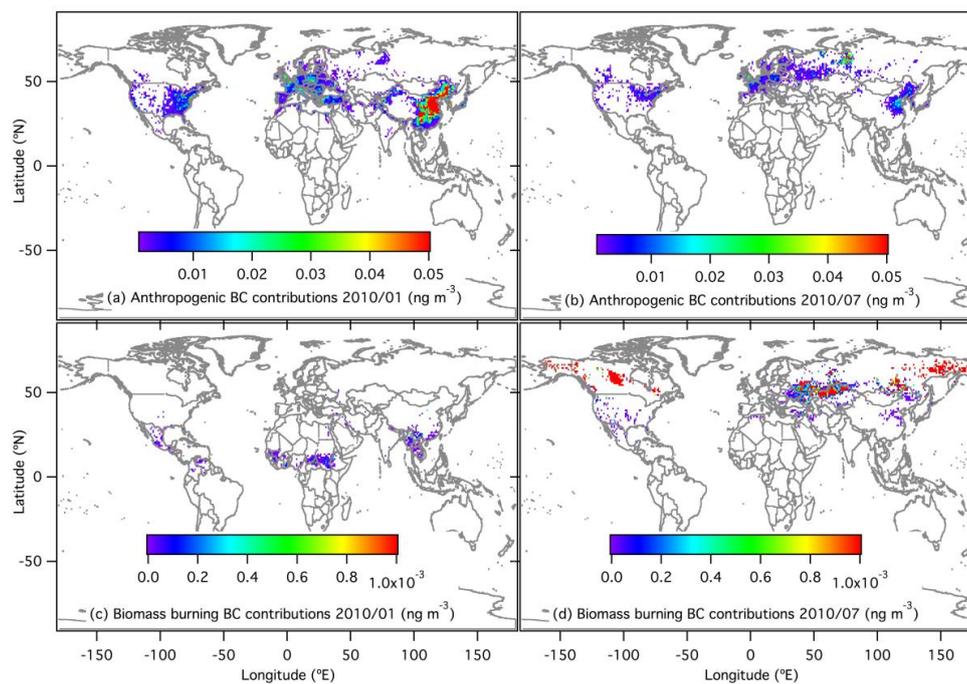

694

695

696 Figure 5. Spatial distributions of contributions to Arctic BC at surface (0–500 m) for (a)
697 anthropogenic contributions in January 2010, (b) anthropogenic contributions in July 2010,
698 (c) biomass-burning contributions in January 2010, and (d) biomass-burning contributions in
699 July 2010.

700

701

702 Figure 6. Spatial distributions of contributions to Arctic BC at high altitudes (4750–5250 m)

703 for (a) anthropogenic contributions in January 2010, (b) anthropogenic contributions in July

704 2010, (c) biomass-burning contributions in January 2010, and (d) biomass-burning

705 contributions in July 2010.
